hard class problem

ABSTRACT

Domain adaptation (DA) aims to transfer knowledge from a label-rich and related domain (source domain) to a label-scare domain (target domain). Pseudo-labeling has recently been widely explored and used in DA. However, this line of research is still confined to the inaccuracy of pseudo-labels. In this paper, we explore the imbalance performance between various classes in-depth and observe that the worse performances among all classes are likely to deteriorate further in the pseudo-labeling, which not only harms the overall transfer performance but also restricts the application of DA when the worse performance among all classes is concerned. To alleviate this problem, we propose a novel framework, called Hard Class Rectification Pseudo-labeling (HCRPL), from two aspects. First, we propose a simple yet effective scheme, named Adaptive Prediction Calibration (APC), to calibrate the predictions of the target samples. Then, we further consider that the predictions of target samples, especially ones belonging to the hard classes, are vulnerable to perturbations. To prevent these samples to be misclassified easily, we introduce Temporal-Ensembling (TE) and Self-Ensembling (SE) to obtain consistent predictions. The proposed method is evaluated in both unsupervised domain adaptation (UDA) and semi-supervised domain adaptation (SSDA). The experimental results on several real-world cross-domain benchmarks, including ImageCLEF, Office-31, Office+Caltech, and Office-Home, substantiates the superiority of the proposed method.

1. Introduction

Over the last few years, Deep Neural Networks (DNNs) [26] achieved impressive performance in machine learning tasks, such as computer vision [20], speech recognition [1], **medical analysis** [66], and so on. Nevertheless, collecting and annotating large-scale training data in distinct domains for various applications is an expensive and labor-intensive process. Meanwhile, the applications of DNNs are greatly limited because the learned network shows poor generalization ability when it encounters new environments. Domain adaptation (DA) [37] serves as an ideal solution for addressing this problem. It has raised widespread attentions [2, 14] in the machine learning community.

The majority of the existing DA methods [19, 31, 13, 14, 50, 39, 55, 49, 47] were devoted to aligning source and target features by decreasing the domain divergence, and these methods can be supported by the theoretical analysis of DA [2]. However, there are still two main limitations with these approaches: 1) methods of global alignment of the source and target feature distribution cannot guarantee correctly alignment of class-level representations, and 2) global alignment methods cannot learn target-discriminative representations. Therefore, it is necessary to align the class conditional distributions of the source and target domains. However, directly pursuing the alignment of class conditional distributions is not possible due to the absence of target labels.

Pseudo-labeling [27] was first employed for semi-supervised learning tasks. Recently, pseudo-labeling was introduced into DA to solve the aforementioned **limitations** by

Figure 1: Hard class problem in existing pseudo-labeling based DA methods: Compared with class 1 and 2, class 3 has lower predictive class proportion. Meanwhile, for this class, target samples with higher confidence are mainly classified into class 1.

alternatively selecting target samples with high confident predictions as the pseudo-labeled target set (labeling phase) and training the model with the source domain and pseudo-labeled target set (training phase). Although pseudo-labeling is considered to be a promising paradigm, it is still limited due to the inevitable false pseudo-labels. Zhang et al. [63] demonstrated that false labels are easily fit by DNN, which harms generalization. Retraining DNN with false pseudo-labeled samples does not guarantee the generalization ability for the target domain. We further analyze the theory of DA [2] in Section 3 and demonstrate that the expected error on the target domain is determined by the false pseudo-labels ratio (i.e., (the number of incorrectly pseudo-labeled samples)/(the number of pseudo-labeled samples)). Therefore, reducing the false pseudo-labels ratio is of crucial importance to pseudo-labeling methods. To achieve

✉ yhuang2010@xmu.edu.cn (Y. Huang)
ORCID(s):

this, Zou et al. [68] enhanced pseudo-labeling from two aspects. 1) They introduced self-paced learning which generates pseudo-labels from easy to hard to alleviate the error accumulation of the pseudo-labels. 2) They utilized different confidence thresholds to select a target pseudo-labeled set for different classes. Zou et al. [67] then introduced confidence regularization to avoid overconfident labels. Saito, Ushiku, and Harada [44] adopted two classifiers with a multiview loss to label the target domain and used a fixed confidence threshold to pick up reliable pseudo-labels. Some works [59, 6, 9, 7] generate pseudo-labels in the feature space and adopt different distances to measure confidence.

In this paper, we explore a problem that is unconsidering in the aforesaid methods. As shown in Figure 1, the classifier is trained on the source domain, and three classes deliver distinct performances. Class 1 belongs to easy classes and has a higher predictive class proportion (i.e., (the number of samples classified into a certain class)/(the number of target samples)). The target samples belonging to these classes are very likely to be classified correctly without extra manipulation. The classifier trained on the source domain can well generalize to the target domain for these classes. Class 2 belongs to normal classes and has a moderate predictive class proportion. Although some the target samples belonging to it are misclassified, the predictions with higher confidence have higher accuracy. Therefore, the existing pseudo-labeling methods [68, 67, 44, 59, 6, 9, 7] progressively improve the performance on these classes by adding the samples with higher confident predictions into training. Class 3 belongs to hard classes and has a lower predictive class proportion. Meanwhile, for hard classes, even the target samples with higher confident predictions also are highly possible to be misclassified, adding these samples into training will misguide the classifier. Therefore, the pseudo-labeling methods cannot improve the performance of the hard classes even will deteriorate it, which is the main difference between the normal and hard classes.

To tackle the hard class problem, we present a simple yet effective scheme, named Adaptive Prediction Calibration (APC), and it calibrates the predictions of target samples to promote the hard classes, to maintain the normal class, and to attenuate the easy classes. Furthermore, the model is vulnerable to the target samples belonging to the hard classes since they are far away from the source domain [52]. Despite encountering a small perturbation (e.g., different augmentations, different classifiers), the predictions of target samples belonging to the hard classes are changed drastically. Worse, the APC will further magnify the unrobustness of predictions for hard classes since their predictions are enlarged proportionally. To ensure the reliability of predictions, we propose two ensembling methods, Temporal-Ensembling (TE) and Self-Ensembling (SE).

Besides, the proposed schemes can be directly combined with the existing pseudo-labeling methods. In this paper, based on the CBST [68], we propose a novel pseudo-labeling framework, which combines APC, SE, and TE to alleviate the hard class problem. The proposed framework is called

Hard Class Rectification Pseudo-labeling (HCRPL).

The main contributions of this work can be summarized as follows:

- i) We reveal the hard class problem in DA, which harms the performance of pseudo-labeling and restricts its applications.
- ii) We propose a calibration method (i.e., APC) to alleviate the hard class problem by promoting the hard class and attenuating the easy one. Furthermore, the predictions are vulnerable because of distribution mismatch and deviation magnification resulting from APC. Hence, we introduce TE and SE to improve the robustness of predictions.
- iii) We evaluate the proposed HCRPL on three public datasets under both UDA and SSDA settings. Extensive experimental results show that the proposed HCRPL achieves promising results in various DA scenarios. Especially under the SSDA setting, the proposed HCRPL outperforms the state-of-the-art methods. More importantly, the further analysis illustrates our approach can alleviate the hard class problem.

2. Related Work

2.1. Unsupervised Domain Adaptation

Under the UDA setting, we are given a set of labeled source samples and a set of unlabeled target examples. According to Ben-David et al.'s [2] theoretical analysis of DA, the expected error for the target domain depends on three terms: the expected error on the source domain, the domain divergence, and the shared error of the ideal joint hypothesis, can divide UDA methods into two parts. In the first part, researchers assumed that the shared error of the ideal joint hypothesis was small and mainly focused on decreasing the domain divergence. One method of aligning distributions is through minimizing the statistical divergence that measures the distance between the distributions. Some representative divergences include Maximum mean discrepancy (MMD) [19], Correlation alignment (CORAL) [49], Contrastive domain discrepancy (CCD) [23], and so on. Inspired by GAN [17], numerous methods [13, 14, 50, 39, 55, 49, 47] were proposed to confuse the source and target domains by an adversarial objective. Although the source and target domains are aligned well, the shared error of the ideal joint hypothesis will be large if the class conditional distributions are not aligned and separated. In the second part, researchers paid more attention to decreasing the shared error of the ideal joint hypothesis. Among the many schemes, pseudo-labeling is a promising paradigm for reducing the third term. Saito, Ushiku, and Harada [44] adopted two classifiers to label the target set and made a constraint for the weight of two classifiers to make their different from each other. Zou et al. [68] introduced self-paced learning which generates pseudo-labels from easy to hard to alleviate the error accumulation of the pseudo-labels. Furthermore, they utilized different confidence thresholds to

select target pseudo-labeled set for different classes. Zou et al. [67] introduced confidence regularization to prevent putting overconfident label belief in the wrong classes. On par with these methods that generate pseudo-labels based on predictions, some methods generate pseudo-labels in the feature space. Xie et al. [59] introduced feature centroids alignment after pseudo-labeling to DA. Chen et al. [6] proposed a progressive feature alignment that takes advantages of intra-class distribution variance in pseudo-labeling for UDA problems. Deng, Zheng, and Jiao [9] introduced the similarity-preserving constraint that can be implemented by minimizing the triplet loss with labeled source features and pseudo-labeled target features. Li et al. [30] introduced the label propagation to update the pseudo-labels and proposed landmark selection to re-weight the samples of source and target domains. Wu et al. [57] determined the pseudo labels by integrating the predictions of multiple classifiers. Chen et al. [8] improved the quality of the pseudo labels by refining the labels after each iteration.

2.2. Semi-Supervised Domain Adaptation

Since most DA methods focus on the unsupervised setting, SSDA has not been well studied. Under the SSDA setting, a set of labeled source samples, a "small" set of the labeled target set, and plenty of unlabeled target examples are given. For SSDA, the key to improving performance is learning the target-discriminative representations. In Saito et al.'s study [43], the standard UDA methods [13, 32, 45] were shown to be empirically less effective in SSDA because they fail to learn discriminative class boundaries on the target domain. By optimizing a minimax loss on the conditional entropy of unlabeled data and the task loss, Saito et al. [43] reduced the distribution gap while learning discriminative features. Motiian et al. [35] exploited the Siamese architecture to learn an embedding subspace that is discriminative and where mapped visual domains are semantically aligned and yet maximally separated. Qin et al. [40] proposed a framework consisting of a generator and two classifiers, where one is a source-based classifier and the other is a target-based classifier. The target-based classifier attempts to cluster the target features to improve intra-class density and enlarge inter-class divergence; the source-based classifier is designed to scatter the source features to enhance the smoothness of the decision boundary. Yan et al. [61] proposed a semi-supervised entropic Gromov-Wasserstein discrepancy approach to incorporate the supervision information when learning the optimal transport.

3. Hard Class Problem

In this section, we first design the experiments to confirm the existence of the hard class problem and then emphasize the significance of alleviating it from two practical aspects.

We first set "Webcam" as the source domain and "Amazon" as the target domain and adopt CBST to solve the domain shift problem between them. To investigate the class-

level performance, we choose precision, recall, and f1-score as metrics and report the results in Figure 6. Compared with training on source domain only, CBST enhances the performances on the majority of classes. We further observe the classes with lower precision, recall, or f1-score (e.g. 4-th and 28-th classes). These classes are so-called hard classes since low precision represents that massive predictions with high confidence are false, and low recall represents those correct predictions with high confidence are small. As a result, CBST has a certain probability to further deteriorate the performance of these classes, which certifies that the hard class problem may further worsen the performance for this class.

Next, we emphasize two problems caused by the hard class problem. Firstly, it is noteworthy that the worst performance among all classes is more concerned rather than the average one in many applications. For instance, in the application of transfer the knowledge of anomaly detection from source domain to target one, we expect to detect the anomalies of every type, but the hard class problem will lead to the poor performance of hard classes. Secondly, the hard class problem also will have negative effect on overall transfer performance, and our explanation is based on Ben-David et al.'s [2] theoretical analysis of DA.

Theorem 3.1. *Let H be the hypothesis class. Given two different domains S and \mathcal{T} , we have*

$$\forall h \in H, R_{\mathcal{T}}(h) \leq R_S(h) + \frac{1}{2}d_{H\Delta H}(S, \mathcal{T}) + C, \quad (1)$$

where the expected error on the target samples $R_{\mathcal{T}}(h)$ are bounded by three terms: (1) the expected error on the source domain, $R_S(h)$; (2) $d_{H\Delta H}(S, \mathcal{T})$ is the domain divergence measured by a discrepancy distance between the source domain distribution S and the target domain distribution \mathcal{T} w.r.t. a hypothesis set H ; and (3) the shared error of the ideal joint hypothesis C . $C = \min_{h \in H} [\epsilon_S(h, f_S) + \epsilon_{\mathcal{T}}(h, f_{\mathcal{T}})]$, and $\epsilon_S(h)$ is the expected error of h on the source domain.

In this study, we focus on the third term that is the shared error of the ideal joint hypothesis C . According to triangle inequality for classification error [2], that is, for any labeling functions f_1, f_2 and f_3 , we have $\epsilon(f_1, f_2) \leq \epsilon(f_1, f_3) + \epsilon(f_2, f_3)$, we could have

$$\begin{aligned} C &= \min_{h \in H} \epsilon_S(h, f_S) + \epsilon_{\mathcal{T}}(h, f_{\mathcal{T}}) \\ &\leq \min_{h \in H} \epsilon_S(h, f_S) + \epsilon_{\mathcal{T}}(h, f_{\mathcal{T}_l}) + \epsilon_{\mathcal{T}}(f_{\mathcal{T}_l}, f_{\mathcal{T}}), \end{aligned} \quad (2)$$

$\epsilon_S(h, f_S) + \epsilon_{\mathcal{T}}(h, f_{\mathcal{T}_l})$ denotes the shared error of h^* on the source domain S and pseudo-labeled set \mathcal{D}_l and is minimized by the training model with the source domain S and pseudo-labeled set \mathcal{D}_l . $\epsilon_{\mathcal{T}}(f_{\mathcal{T}_l}, f_{\mathcal{T}})$ denotes the false pseudo-labels ratio. Overall, the expected error on the target domain is determined by the false pseudo-labels ratio.

Next, we link the hard class problem with the false pseudo-labels ratio from the following two aspects. Firstly, few target samples are classified into hard classes, and the model

cannot learn to target discriminative representations for the hard classes. Secondly, the hard class problem will cause error accumulation and increase the false pseudo-labels ratio since pseudo-labeling may select false predictions with high confidence, and then these false predictions will misguide the classifier.

4. Methods

4.1. Preliminary

This section describes HCRPL based on the UDA setting. Under UDA setting, a source domain $D_s = \{(x_i^s, y_i^s)\}_{i=1}^{m_s}$ and a target domain $D_u = \{(x_i^u)\}_{i=1}^{m_u}$ are given. We define the pseudo-labeled set as $D_l = \{(x_i^u, \hat{y}_i^u)\}_{i=1}^{m_l}$. Specifically, y_i^s and \hat{y}_i^u are one-hot vectors. Meanwhile, we assume that the source domain and target domain contain the same object classes, and we consider C classes. Under SSDA setting, the source domain and labeled target set are regarded as the new source domain while the unlabeled target set is regarded as the new target domain.

The proposed HCRPL belongs to pseudo-labeling, but it is different from the standard pseudo-labeling where the target samples are predicted after every epoch but not every round. To describe the proposed HCRPL more clearly, the labeling phase is divided into predicting and selecting phases. The overall training process is given in Algorithm 1 and Figure 2, and mainly includes three phases as follows:

- 1) Training phase: training network with the training set D_{tr} .
- 2) Predicting phase: generating the ensemble predictions Z obtained from the target domain D_u .
- 3) Selecting phase: selecting confident predictions as the pseudo-labeled set D_l .

We define going through the process from training the network to updating D_{tr} once as one round. The proposed APC, TE, and SE are included in the predicting phase. The overall training process along with APC, TE, and SE are introduced below.

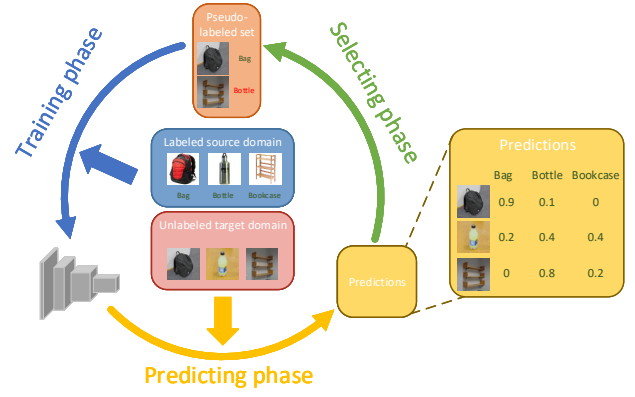

Figure 2: The overall framework of the proposed HCRPL, which mainly is composed of training, predicting, and selecting phases. The whole framework undergoes these three phases alternatively.

4.2. Adaptive Prediction Calibration

Adaptive prediction calibration is the core component in our approach. In the hard class problem, target samples are prone to be classified into easy classes and difficult to be classified into hard ones, which leads to the lower predictive class proportion for hard classes. One way to alleviate this problem is magnifying the predictive proportions of hard classes, keeping the normal ones, and suppressing the easy ones. To control predictive class proportions in a reasonable interval, we try to eliminate the mismatch between the predictive class proportion and the true one of the target domain, which always is unknown in practice. Here, we replace it with the class proportion of the source domain, which is reasonable due to the following two aspects. First, the label proportions of the source and target domains always are close, which is valid in many practical applications. Second, we demonstrate that the minor disagreement between the label proportions of the source and target domains slightly affects the transfer performance by experiments, the details of which are shown in 5.6.1.

The detailed process of APC is shown in Figure 3 top. The target domain D_u is first fed into the trained model to obtain the predictions $P = \{p_i^u\}_{i=1}^{m_u}$. Then, we define a ratio R of class distribution of source domain $q(y)$ to the predictive class distribution $p(y)$ as follows

$$R = q(y) \oslash p(y), \quad (3)$$

where $q(y) = \frac{1}{m_s} \sum_{i=1}^{m_s} y_i^s$, $p(y) = \frac{1}{m_u} \sum_{i=1}^{m_u} p_i^u$ and \oslash means element-wise division, and R is a C -dimensional vector with i -th dimension being the difficulty degree belonging to i -th class. Finally, we calibrate predictions P by

$$P \leftarrow \{\text{Normalization}(R \odot p_i^u)\}_{i=1}^{m_u}, \quad (4)$$

where $\text{Normalization}(x) = \frac{x}{\sum_i x_i}$ and \odot means element-wise multiplication. Intuitively, we calibrate P by R . For a certain class c , if the predictive probability of class c is small,

APC**TE****SE**

Figure 3: Structure of the training pass in HCRPL. Top: APC. Middle: TE. Bottom: SE. the details of Eq.1., Eq.2., Eq.3. and Eq.4. are show in Equal 3, 4, 5 and 7.

which means that class c is a hard class, the APC will increase the probabilities of classifying target samples into class c .

4.3. Temporal-Ensembling and Self-Ensembling

To ensure the reliability of predictions, two ensembling methods, TE and SE, are adopted to improve the robustness of predictions of target samples. For TE, integrating predictions of multiple classifiers is considerable to obtain consistent predictions. Different from that Saito, Ushiku, and Harada [44] constructed two classifiers with multiview loss, in this paper, we adopt the temporal-ensembling based method which views the trained model after different epochs as different classifiers and there is no need to construct multiple classifiers. As shown in Figure 3 middle, we evaluate the target domain after every epoch and update the ensemble predictions z_i by Exponential Moving Average (EMA). The EMA can be formulated as

$$z_i \leftarrow \alpha z_i + (1 - \alpha) p_i^u. \quad (5)$$

The EMA could memorize all predictions and place a greater weight on the most recent predictions. α is the EMA momentum, and recent predictions will have a higher proportion with a lower α . If $\alpha = 0$, then the ensemble predictions z_i are equal to the current predictions p_i^u . Specifically, the ensemble predictions z_i are used to select pseudo-labeled samples in the selecting phase.

For SE, we integrate the predictions of two different augmentations. As shown in Figure 3 bottom, we feed the target samples into the trained model twice with different stochastic augmentations and obtain predictions p_{i1}^u and p_{i2}^u . Then, the average predictions $\frac{p_{i1} + p_{i2}}{2}$ are calculated. To obtain lower entropy predictions, we perform an additional

step, named Sharpening [4, 3]. It is defined as the operation

$$\text{Sharpen}(p, T) = \text{Normalization}(p^{1/T}), \quad (6)$$

where T is named as the sharpening temperature. When T is smaller, the predictions with lower entropy are obtained. Finally, we obtain the predictions P by

$$P = \text{Sharpen}\left(\frac{P_1 + P_2}{2}, T\right). \quad (7)$$

TE and SE are somewhat similar to Π -model [25] and Mean Teacher [12, 54]. These methods took the difference of the predictions of different epochs and augmentations as a regularization term to constrain the model. Our aim is different from these methods. We expect to improve the robustness of predictions by enforcing the predictions of different augmentations and epochs consistency.

4.4. Overall Training Process

The details of the training, predicting, and selecting phases are described below.

In the training phase, the network is trained with training dataset D_{tr} . In the first round, we view D_s as D_{tr} and subsequently update D_{tr} with the pseudo-labeled target set D_l and source domain D_s . The training objective is defined as

$$L = \frac{1}{m_s + m_t} \left(\sum_{i=1}^{m_s} H(y_i^s, p_i^s) + \sum_{i=1}^{m_t} H(\hat{y}_i^u, p_i^u) \right), \quad (8)$$

where $H(p, q)$ is the standard cross-entropy loss function. With the number of pseudo-labeled target samples increasing, the network learns more of the target-discriminative

representations and gradually enhances the transfer performance in the target domain.

Algorithm 2 Details of the prediction process

Require: ensemble predictions shadow value Z , prior class proportion $q(y)$, target domain D_u , network parameter θ , EMA momentum α .

12:  $P = \text{Sharpen}(\frac{P_1 + P_2}{2}, T)$ 
13:  $Z \leftarrow \alpha Z + (1 - \alpha)P$ 
14: return  $Z$ 

```

In the predicting phase, we aim to improve the accuracy and robustness of predictions, especially for the hard classes. We propose the APC, TE, and SE to adjust the predictions of target samples. The overall workflow pseudocode for the predicting phase is given in Algorithm 2. The predicting phase can be split into five parts: Firstly, the target set is augmented twice and the corresponding predictions P_1, P_2 are obtained (Line 2-7). Secondly, the difficulty ratio R of prior class proportion $q(y)$ to predictive class distribution $p(y)$ is calculated (Line 8-9). Thirdly, the APC is applied to calibrate predictions P_1, P_2 (Line 10-11). Fourthly, the average predictions $\frac{P_1 + P_2}{2}$ are calculated (Line 12). Finally, the ensemble predictions Z are updated by EMA (Line 13).

In the selecting phase, we select the predictions of target samples with higher confidence as pseudo-labels. CBST [68] considers that different classes should have different confidence thresholds and dynamically adjusts thresholds to generate pseudo-labels from easy to hard. The class-balanced self-training solver can be formulated as

$$y_{ic}^u = \begin{cases} 1, & \text{if } c = \arg\max_c \frac{z_{ic}^u}{\exp(-k_c)}, \\ \frac{z_{ic}^u}{\exp(-k_c)} > 1, & \\ 0, & \text{otherwise.} \end{cases} \quad (9)$$

Here, z_i^u means the ensemble predictions of i -th sample in the target domain. z_{ic}^u means the ensemble probability for the c -th class in z_i^u . k_c for each class c is determined by a single portion parameter p that indicates how many samples to select in the target domain. Practically, p is gradually increased to select more pseudo-labeled samples for each

round. For a detailed algorithm, we recommend reading Algorithm 2 in Zou et al.'s paper [68].

5. Experiments

5.1. Datasets

5.1.1. ImageCLEF-DA

ImageCLEF-DA¹ is a benchmark dataset for ImageCLEF 2014 DA challenges. Three domains, including Caltech-256 (C), ImageNet ILSVRC 2012 (I), and Pascal VOC (P), share 12 categories. Each domain contains 600 images and 50 images for each category.

5.1.2. Office-31

Office-31 [42] is a standard benchmark for DA tasks. The dataset contains 4110 images of 31 categories collected from three domains: Amazon (A), Webcam (W), and Dslr (D). Under SSDA setting, we followed the settings used by Saito et al. [43] and then evaluated the proposed method on the task between $W \rightarrow A$ and $D \rightarrow A$.

5.1.3. Office+Caltech

Office+Caltech [16] is a common benchmark that consists of four domains: Caltech, Amazon, Webcam, and Dslr. These four domains share images from ten categories. There are 2533 images in total.

5.1.4. Office-Home

Office-Home [56] is a more challenging DA dataset compared to Office-31. It consists of 15500 images from 65 categories and is organized into four domains: Art (Ar), Clipart (Cl), Product (Pr), and Real-world (Rw).

We show examples of four datasets in Figure 4. We can see different classes have different domain shift. For example, in Office-Home, the examples of class 'Alarm-Clock' from different domains are similar to each other whereas the examples of class 'Backpack' vary a lot.

5.2. Baselines

5.2.1. Unsupervised Domain Adaptation

For Office+Caltech, we set AlexNet [24] as backbone and compare our approach with traditional and deep methods, such as SA [11], GFK [16], TCA [36], SCA [15], LPJT [22], KJDIP-rbf [8], FSDA [51], MMD-CORAL [41], and GKE [58]. For the remaining datasets, we evaluated HCRPL with ResNet-50 [20]. We compared the proposed HCRPL with the latest methods, including Reverse Gradient (RevGrad) [13], Joint Adaptation Networks (JAN) [33], Class-Balanced Self-Training (CBST) [68], Confidence Regularized Self-Training (CRST) [67], CDAN [32], SAFN [60], Domain-Symmetric Networks (SymNets) [65], Domain adversarial neural network (DANN) [14], Discriminative Adversarial Domain Adaptation (DADA) [53], MDD [64], Maximum Classifier Discrepancy (MCD) [46] and Cycle-consistent Conditional Adversarial Transfer Networks (3CATN) [28].

¹<http://imageclef.org/2014/adaptation>

Figure 4: Example images in ImageCLEF-DA, Office-31, Office+Caltech, and Office-Home

5.2.2. Semi-Supervised Domain Adaptation

In the SSDA experiment, we evaluated the proposed model with **AlexNet** [24] and **VGG16** [48]. The proposed model was compared with Domain adversarial neural network (DANN) [14], **CDAN** [32], **ENT** [18], Adversarial dropout regularization (**ADR**) [45], and the Minimax Entropy (**MME**) [43].

5.3. Implementation Details

The proposed HCRPL was implemented with PyTorch². For a fair comparison, our backbone network was the same as the competitive methods. For AlexNet, we replace the last full-connected layer with a randomly initialized bottleneck layer which consists of two full-connected layers: $4096 \rightarrow C$. For VGG and ResNet, we replace the last full-connected layer with a randomly initialized C -way classifier layer. It was pre-trained on ImageNet and then fine-tuned using SGD with a weight decay of 5×10^{-4} , momentum of 0.9, and batch size of 32. Likewise, we used horizontal-flipping and random-cropping based data augmentation for all the training data. For the pseudo-labeling setting, we set the total number of pseudo-labeling rounds to be 30, each with 20 epochs. In the r -th round, we choose the top $p\%$ of the highest confidence target samples within each category, and $p = \min(r * 5 + 10, 90)$. In the first round, the network was trained with labeled data (source domain in UDA; source domain and labeled target data in SSDA) with a learning rate of 5×10^{-5} or 1×10^{-4} . Furthermore, it was then retrained in the subsequent rounds with a learning rate of 1.5×10^{-5} . We set the EMA momentum α to 0.95. Under the SSDA setting, we added a few-shot module to AlexNet and VGG16 like Saito et al. [43] for better comparison with MME.

5.4. Results

5.4.1. Unsupervised domain adaptation

The transfer performances on the Office-Home, Office-31, Office+Caltech, and ImageCLEF-DA under UDA setting are shown in Table 1, 2, 3, and 4, respectively. For Office-Home, the result is shown in Table 1, and HCRPL outperforms the best performance by 2.8% on average and achieves state-of-the-art performance on most tasks. It should be noted that the proposed framework has a larger improvement on the transfer tasks with larger domain shift. For example, the tasks $Ar \rightarrow Cl$ and $Cl \rightarrow Ar$ have poor generalization ability on the target domain, and HCRPL has an improvement over MDD by 5.4% on $Ar \rightarrow Cl$ and 7.2% on $Cl \rightarrow Ar$. For Office-31, we report the averages and standard deviations of the evaluation results over 3 runs. HCRPL outperforms all the other methods on $A \rightarrow W$, $A \rightarrow D$, $D \rightarrow A$, $D \rightarrow A$, and the average of all the sub-tasks. For Office+Caltech, except for AlexNet based deep methods, our approach also compares with the shallow methods, which replace the image input with features extracted by Decaf [10] or VGG [48]. In general, deep methods are better than shallow ones, and our approach further outperforms some existing deep methods. For ImageCLEF-DA, HCRPL outperforms all the other methods on $I \rightarrow P$, $P \rightarrow I$, $C \rightarrow I$, $C \rightarrow P$, $P \rightarrow C$, and the average of all sub-tasks.

5.4.2. Semi-supervised domain adaptation

We show results on Office-31 and Office-Home under the SSDA setting. As shown in Table 5 and 9, the proposed HCRPL achieves the state-of-the-art performance on all settings (e.g., different networks, different labeled target sample size) and sub-tasks. Specifically, on Office-31 1-shot, HCRPL outperforms MME by 5.8% using AlexNet. As a reference, MME outperforms S+T by 6.3% under the same setting. Training with AlexNet is more challenging than VGG, but HCRPL improves more on AlexNet, which also proves the effectiveness of HCRPL in challenging scenarios. Similarly, under the SSDA setting, HCRPL has a larger improvement on the tasks with larger domain shift.

5.4.3. Comparisons with CBST

Tables 1, 2, 4, 5 and 9 also provide the results of CBST on different tasks. HCRPL not only outperforms on all tasks but also improves performance by a large margin compared to CBST, which implies that HCRPL promotes overall compared to CBST. Specifically, we discover that the perfor-

mance improvements are more visible on hard tasks (for example, A \rightarrow D in Office-31), which illustrates that the hard class problem will further deteriorate the performance of pseudo-labeling in the case of large domain shift, and the proposed HCRPL could alleviate it.

Figure 5: (a)-(c): The t-SNE visualization of features generated by Source-only, CBST, and HCRPL (purple: source, yellow: target). The result is obtained on Office-31 A \rightarrow W under UDA setting using ResNet-50. (d)-(e): Comparison of the actual accuracy of pseudo-labels and learned network accuracy during training.

5.5. Ablation Study

We conduct the ablation study under four different settings. The results are shown in Table 6. As shown, the APC module plays the most important role in HCRPL. The large performance degradation without APC indicates that calibrating the predictions of target samples is effective to improve transfer performance. Besides, SE and TE could further improve performance by improving the robustness of predictions. Meanwhile, it is found that the accuracy of the pseudo-labels varies similarly without SE or TE, which illustrates that they perform similar roles. Moreover, the performance of CBST is much lower than the proposed methods, which proves that the hard class problem deteriorates transfer performance dramatically and the proposed schemes

are effective.

5.6. Analysis

5.6.1. The effect of different prior class proportions.

We respectively set marginal class proportion of the source and target domains as prior class proportion and report the results in Table 7. The overall transfer accuracy of the former is only 0.4% lower than the latter, which supports that adopting the former to calibrate the predictions is reasonable when the latter is unknown.

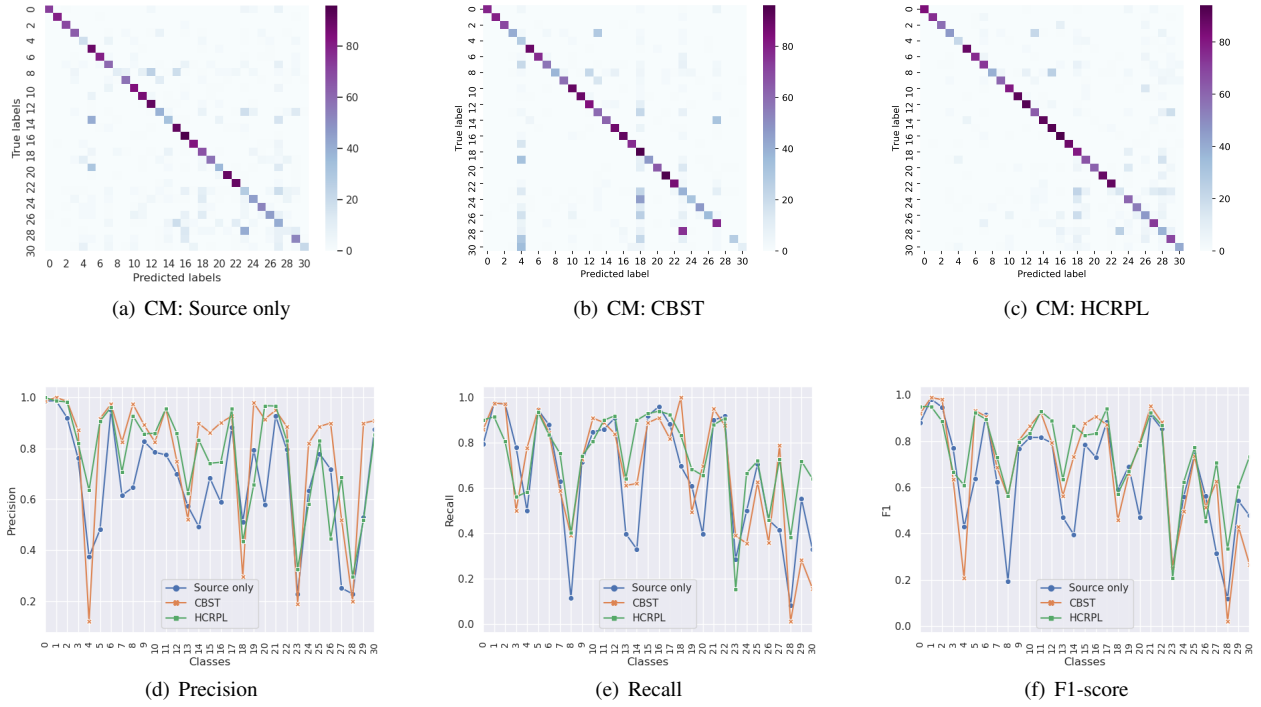

Figure 6: (a)-(c) The Confusion Matrix (CM) visualization for Source only, CBST, and HCRPL. (d)-(f): The precision, recall, and f1-score evaluated on three different models, Source-only, CBST, and HCRPL. The result is obtained on Office-31 W \rightarrow A under UDA setting using ResNet-50. To better visualize the results, we arrange the categories in alphabetic order.

Table 5

Results on the Office-31 datasets under SSDA setting(%)

	HCRPL	74.6	77.2	74.0	77.8

5.6.2. Pseudo-labeling Accuracy.

We report the accuracy of pseudo-labels and learned network during training on Office-31 A \rightarrow W and Office-Home Pr \rightarrow Cl under UDA setting in Figure 5(d) and 5(e), respectively. We found that (1) As training processes, the test accuracy increases steadily, which illuminates the stability of

Table 6

Ablation study under four settings. U and S denote UDA and SSDA, respectively; and R and A denote ResNet50 and AlexNet, respectively. 1 means 1-shot. w/o means without.

Methods	Cl \rightarrow Ar UR	A \rightarrow W UR	Rw \rightarrow Cl SA1	D \rightarrow A SV1
CBST	56.5	87.0	39.7	62.4
HCRPL w/o APC	62.3	88.6	40.4	65.1
HCRPL w/o SE	66.6	92.5	45.3	68.8
HCRPL w/o TE	66.2	93.1	44.7	69.1
HCRPL (full)	67.2	95.9	46.0	70.0

our approach, and hence it can adapt to various scenarios better. (2) The test accuracy maintains a tight relationship with accuracy and the number of pseudo labels. In Office-31 A \rightarrow W, the accuracy of pseudo labels keeps stable and the number increases, the test accuracy can keep step with the number of pseudo labels. Office-Home Pr \rightarrow Cl is a quite challenging task, and our approach also can extract positive information and improve the test accuracy in the process of pseudo-labeling.

5.6.3. Exploring the hard classes.

We report the confusion matrix, precision, recall, and f1-score of source only, CBST, and our approach in Figure 6. We first compare the results of Source only and CBST. Al-

Table 7

Comparison of different prior class proportion on Office-31 under UDA setting (%). S denotes the marginal class proportion of the source domain. T denotes the marginal class proportion of the target domain.

prior class proportion	A \rightarrow W	D \rightarrow W	W \rightarrow D	A \rightarrow D	D \rightarrow A	W \rightarrow A	Avg
S	95.9 \pm 0.2	98.7 \pm 0.1	100.0 \pm 0.0	94.3 \pm 0.2	75.0 \pm 0.4	75.4 \pm 0.4	89.9
T	96.3 \pm 0.1	98.9 \pm 0.1	100.0 \pm 0.0	94.9 \pm 0.2	75.5 \pm 0.3	76.2 \pm 0.3	90.3

though the precision, recall, and f1-score of majority classes are better to a certain extent, the worse performances among all classes may deteriorate further. Here, we focus on the performance of 28-th class in the confusion matrix. The majority of samples belonging to this class are misclassified into the 23-th class in the case of training on the source domain only. After pseudo-labeling, the predictions more center on the 23-th class, which results from the misguidance of false predictions with high confidence. The results of precision, recall, and f1-score also confirm this conclusion. Furthermore, we found that the predictive class proportion of easy classes, such as 4-th and 18-th classes, are higher after applying pseudo-labeling (shown in Figures 6(a) and 6(b)), which results in the decline of precision for these classes, which also is the drawback of pseudo-labeling.

We further analyze the performance of our HCRPL from the aspect of hard classes. First, the HCRPL avoids the predictions degenerate into few classes, which illustrates the HCRPL can control the predictive class proportion of each class in a reasonable interval and improve the precision of the easy classes. Second, we found the precision of majority classes, is better than CBST and source only. The recall is flat or slightly better than CBST and source only. Overall, class-level performance exceeds CBST and source only. Especially for hard classes, such as 28-th, and 30-th classes, the performance of HCRPL is superior apparently, which demonstrates that our approach can indeed alleviate the hard class problem.

5.6.4. Feature Visualization.

We train ResNet-50, CBST, and the proposed HCRPL on Office-31 A \rightarrow W under UDA setting and plot the learned features with t-SNE [34] in Figure 5 (a-c), respectively. The purple and yellow points represent the learned features of the source domain and target domain, respectively. As mentioned in the section 1, pseudo-labeling is a promising paradigm for aligning and separating the class conditional distributions of various domains. Therefore, CBST and HCRPL could promote to learn target-discriminative representations and to align the class conditional distributions. Furthermore, HCRPL could learn more of the target-discriminative representations due to improving the accuracy of pseudo-labels.

5.6.5. Convergence.

The convergence of ResNet, CBST, and the proposed HCRPL can be demonstrated by the error rates in the target domain on Office-31 A \rightarrow W under UDA setting. As shown in Figure 7, the following observations can be made:

Figure 7: Test accuracy over iterations. The result is obtained on Office-31 A \rightarrow W under UDA setting using ResNet-50. ResNet means that we train the model without DA and only use the source domain as training data.

Table 8

Comparison of different EMA momentum α and sharpening temperature T on A \rightarrow W.

α	0.0	0.8	0.9	0.95	0.97	0.99
Acc (%)	92.5	93.1	95.2	95.9	94.5	93.1
T	0.2	0.3	0.5	0.7	0.8	1.0
Acc (%)	94.7	95.7	95.9	93.8	93.8	92.3

- 1) CBST and HCRPL are more stable than ResNet (baseline) due to alleviating overfitting to the source domain.
- 2) The target error decreases gradually learned by CBST and HCRPL because the pseudo-labeling methods progressively generate more pseudo-labels and learn more of the target-discriminative representations as the training progresses.
- 3) The disparity of the target error between CBST and HCRPL increases gradually, which indicates that APC, SE, and TE effectively improve the accuracy of pseudo-labels.

5.6.6. Hyperparameter Sensitivity

We then investigate the sensitivity of HCRPL for different choices of hyperparameters: EMA momentum α and sharpening temperature T . The results are reported in Table 8. For EMA momentum α , the transfer accuracy fluctuates slightly when $\alpha \in [0.9, 0.97]$. However, when the value of α does not belong to this range, the transfer accuracy degrades a lot. For sharpening temperature T , the smaller T achieves better performance than the larger one,

which means the predictions with lower entropy are more accurate. Meanwhile, the minimal value of T also degrades the performance.

6. Discussion and Conclusion

6.1. Strength

The major contribution of this paper is unraveling the hard class problem, which always is ignored in the existing pseudo-labeling methods yet is critical in some practical scenarios. Compared with the existing pseudo-labeling methods, our approach improve not only the overall performance but only the worst performance among all classes.

6.2. Weakness

The introduction of prior knowledge alleviates the hard class problem effectively. However, it also limits the application of our approach to a certain extent. Our basic assumption is that the source and target domains should have similar label proportion, which is invalid in some applications, such as partial domain adaptation [5], open set domain adaptation [38]. In such variants of DA, applying APC obviously will miscalibrate the predictions and results in massive false pseudo labels. Therefore, accurately inferring the marginal class distribution of the target domain should be further studied in the future job. On the other hand, the proposed HCRPL can effectively improve the precision of hard classes but has little impact on the recall of them, which also

is important in practical applications.

6.3. Conclusion

Pseudo-labeling is a promising paradigm for solving the DA problem. In this paper, we first revealed the hard class problem may occur in DA and is harmful to the application of DA. To alleviate the hard class problem, we proposed APC to calibrate predictions according to the difficulty degree for each class. Furthermore, we introduced SE and TE to improve the robustness of the predictions of target samples, especially for ones belonging to hard classes. In the experiment, we demonstrated that HCRPL achieved good results and outperformed some state-of-the-art methods with considerable margins under the UDA setting. Meanwhile, HCRPL is suitable for the SSDA setting because it can learn target-discriminative representations. Experimental analysis shows that the proposed schemes can indeed alleviate the hard class problem and improve the accuracy of pseudo-labels.
